17 STAR, steroidogenic acute regulatory protein
18 TGF, transforming growth factor
Abstract

Excess androgen and insulin-like growth factor (IGF)-I in the ovarian follicle has been suggested to be involved in the pathophysiology of polycystic ovary syndrome (PCOS). Here we investigated the impact of androgen and IGF-I on the regulatory mechanism of ovarian steroidogenesis using rat primary granulosa cells. It was revealed that androgen treatment with dihydrotestosterone (DHT) amplified progesterone synthesis in the presence of FSH and IGF-I, whereas it had no significant effect on estrogen synthesis by rat granulosa cells. In accordance with the effects of androgen on steroidogenesis, DHT enhanced the expression of progesterogenic factors and enzymes, including StAR, P450scc and 3βHSD, and cellular cAMP synthesis induced by FSH and IGF-I. Of note, treatment with DHT and IGF-I suppressed Smad1/5/8 phosphorylation and transcription of the BMP target gene Id-1, suggesting that androgen and IGF-I counteract BMP signaling that inhibits FSH-induced progesterone synthesis in rat granulosa cells. DHT was revealed to suppress
the expression of BMP-6 receptors, consisting of ALK-2, ALK-6 and ActRII, while it increased the expression of inhibitory Smads in rat granulosa cells. In addition, IGF-I treatment upregulated androgen receptor (AR) expression and DHT treatment suppressed IGF-I receptor expression on rat granulosa cells. Collectively, the results indicate that androgen and IGF-I mutually interact and accelerate progesterone production, at least in part, by regulating endogenous BMP signaling in rat granulosa cells. Cooperative effects of androgen and IGF-I counteract endogenous BMP-6 activity in rat granulosa cells, which is likely to be functionally linked to the steroidogenic property shown in the PCOS ovary.
**Introduction**

In patients with polycystic ovary syndrome (PCOS), endogenous insulin levels are increased due to insulin resistance [1]. Hyperinsulinemia reinforces local insulin-like growth factor (IGF)-I activity in the ovary and, as a result, this induces an androgenic composition in theca cells [2]. Both increased IGF-I activity and a high androgenic environment appear to be involved in the ovulation disorder in PCOS patients [3].

The growing and maturing process of ovarian follicles occurs as a consequence of functional interactions between gonadotropins and various autocrine/paracrine factors in the ovary. It has been shown that the ovarian bone morphogenetic protein (BMP) system plays a critical role in the regulation of follicular steroidogenesis in an autocrine/paracrine manner [4, 5]. BMPs exert a common biological activity to suppress progesterone synthesis stimulated by follicle-stimulating hormone (FSH) as a luteinizing inhibitor. In growing follicles, exquisite control of FSH responsiveness is necessary for the
physiological selection of dominant follicles and the successive ovulation. BMPs are key regulatory molecules for the maintenance of FSH activity as well as FSH sensitivity during the process of normal folliculogenesis [4, 6].

The BMP system molecules including BMP ligands and the receptors exhibit a cell-specific expression pattern in ovarian follicles. Among these, the expression of BMP-6 is localized in oocytes and granulosa cells at Graafian stages of rat healthy follicles [6]. BMP-6 has an inhibitory effect on FSH receptor actions by suppressing adenylate cyclase, leading to cAMP reduction, in rat granulosa cells [7, 8]. BMP-6 expressed in rat granulosa cells appears to be reduced at the step of selecting dominant follicles [6], suggesting that BMP-6 physiologically conduces to the selection process.

From the standpoint of the pathophysiology of human PCOS, examination of ovary tissues revealed that growth and differentiation factor (GDF)-9 mRNA expression, compared to BMP-15, was delayed and decreased in growing follicles from PCOS ovaries [9]. Moreover, it is of note that the expression of BMP-6 is highly increased in human granulosa cells isolated from
PCOS ovaries [10, 11].

In the present study, we investigated the functional roles of androgen and IGF-I in ovarian steroidogenesis by focusing on BMP-6, which suppresses progesterone biosynthesis, using primary culture of rat granulosa cells. It was clarified that androgen excess and IGF-I action interact mutually and accelerate steroidogenesis by regulating endogenous BMP signaling in rat granulosa cells.
Materials and Methods

Reagents and supplies

McCoy’s 5A medium, Medium 199 and HEPES buffer solution were purchased from Invitrogen Corp. (Carlsbad, CA). Bovine serum albumin (BSA), diethylstilbestrol (DES), dihydrotestosterone (DHT), 4-androstene-3,17-dione, 3-isobutyl-1-methylxanthine (IBMX), insulin-like growth factor-I (IGF-I), ovine pituitary FSH, and penicillin-streptomycin solution were purchased from Sigma-Aldrich Co. Ltd. (St. Louis, MO). Recombinant human BMP-6 was purchased from R&D Systems Inc. (Minneapolis, MN).

Primary culture of rat ovarian granulosa cells

Female Sprague-Dawley (SD) rats were purchased from Charles River (Wilmington, MA). To increase the number of granulosa cells, silastic capsules containing 10 mg of DES were implanted in 22-day-old female SD rats. After 3 days of exposure to DES, ovarian follicles were punctured with a 27-gauge needle. Granulosa cells were counted and separated from oocytes by filtering.
the oocyte/granulosa cell suspension through 100- and 40-μm nylon meshes (BD Falcon, Bedford, MA) that allowed granulosa cells but not oocytes to pass through [12, 13]. The isolated granulosa cells were then cultured in a serum-free McCoy's 5A medium supplemented with penicillin-streptomycin at 37°C in an atmosphere of 5% CO₂. The animal protocols were approved by Okayama University Institutional Animal Care and Use Committee.

**Determination of estradiol, progesterone and cAMP levels**

Rat granulosa cells (1 × 10⁵ viable cells in 200 μl) were cultured, as described above, in 96-well plates with 100 nM of androstenedione, a substrate for aromatase. FSH (10 ng/ml) was added to the culture medium either alone or in combination with indicated concentrations of IGF-I and DHT. After 48-h culture, the culture media were collected and stored at -30°C until assay. The concentrations of estradiol and progesterone in the culture medium were examined by a chemiluminescent immunoassay (CLIA) using Architect estradiol and progesterone kits (Cayman Chemical Co., Ann Arbor, MI, USA).
contents were undetectable (progesterone <10 pg/ml and estradiol <15 pg/ml) in cell-free medium. To evaluate cellular cAMP synthesis, rat granulosa cells (1 × 10^5 viable cells in 200 μl) were cultured, as described above, in 96-well plates with 0.1 mM of IBMX (specific inhibitor of phosphodiesterase activity). After 48-h culture with indicated treatments, the conditioned medium was collected and stored at -30°C until assay. The concentrations of extracellular cAMP were measured by an enzyme-linked immunosorbent assay (ELISA; Enzo Life Sciences, Inc., NY, USA) after acetylation of each sample with assay sensitivity of 0.039 pmol/ml.

*Granulosa cellular RNA extraction and quantitative RT-PCR*

Rat granulosa cells (5 × 10^5 viable cells in 1 ml) were cultured in 12-well plates with serum-free McCoy’s 5A. Cells were treated with FSH (10 ng/ml) either alone or in combination with indicated concentrations of IGF-I and DHT. After 48-h culture, total cellular RNA was extracted using TRIzol® (Invitrogen Corp.). Total RNA amount was quantified by measuring the absorbance of the sample at
260 nm, and stored at -80°C until assay. Primer pairs for activin receptor-like kinase (ALK)-2, ALK-3 and ALK-6, activin type-II receptor (ActRII), BMP type-II receptor (BMPRII), Smad6 and 7, and ribosomal protein L19 (RPL19) were selected as reported previously [14, 15]. For all of the genes, the primer pairs were selected from different exons of the corresponding genes to distinguish PCR products that might arise from chromosome DNA contaminants as follows: P450scc, 147-167 and 636-655 (from GenBank accession #J05156); steroidogenic acute regulatory protein (StAR), 395-415 and 703-723 (AB001349); rat type-I 3β-hydroxysteroid dehydrogenase (3βHSD), 336-355 and 841-860 (M38178); P450arom, 1180-1200 and 1461-1481 (M33986); Id-1, 225-247 and 364-384 (NM_010495); IGF-I receptor (IGF-IR), 1266-1287 and 1501-1522 (NM_052807); androgen receptor (AR), 2521-2543 and 2711-2734 (NM_013476); and RPL19, 401-421 and 575-595 (J02650). The extracted RNA (1 μg) was subjected to reverse transcription using a First-Strand cDNA Synthesis System (Invitrogen Corp.) with random hexamer (2 ng/μl), reverse transcriptase (200 U) and deoxynucleotide triphosphate (dNTP; 0.5 mM) at 42°C.
for 50 min and at 70°C for 10 min. To quantify the level of target gene mRNA, real-time PCR was performed using the LightCycler® Nano real-time PCR system (Roche Diagnostic Co., Tokyo, Japan) after optimization of annealing conditions. The relative mRNA expression was calculated by the Δ threshold cycle (Ct) method, in which ΔCt is the value obtained by subtracting the Ct value of RPL19 mRNA from the Ct value of the target mRNA, and the amount of target mRNA relative to RPL19 mRNA was expressed as $2^{-(\Delta Ct)}$. The data are expressed as the ratio of target mRNA to RPL19 mRNA.

**Western immunoblotting analysis**

Rat granulosa cells (2.5 × 10⁵ viable cells in 500 μl) were cultured in 24-well plates in serum-free McCoy’s 5A medium. After preculture either alone or with indicated concentrations of IGF-I and/or DHT, cells were treated with BMP-6 for 60 min. The cells were solubilized in 100 μl RIPA lysis buffer (Upstate Biotechnology, Lake Placid, NY) containing 1 mM Na₃VO₄, 1 mM NaF, 2% SDS, and 4% β-mercaptoethanol. The cell lysates were subjected to
SDS-PAGE/immunoblotting analysis using anti-phospho-Smad1/5/8 (pSmad1/5/8) antibody (Cell Signaling Technology, Inc., Beverly, MA) and anti-actin antibody (Sigma-Aldrich Co. Ltd.). The integrated signal density of each protein band was analyzed by the C-DiGit® Blot Scanner System (LI-COR Biosciences, NE). To evaluate the target protein levels, the ratios of the signal intensities of target proteins / actin were calculated.

Statistical analysis

All results are shown as means ± SEM of data from at least three separate experiments, each performed with triplicate samples. Differences between groups were statistically analyzed using ANOVA or unpaired t-test, when appropriate (StatView 5.0 software, Abacus Concepts, Inc., Berkeley, CA). If differences were detected by ANOVA, Fisher’s protected least significant difference (PLSD) test and Tukey-Kramer’s post hoc test were used to determine which means differed (StatView 5.0 software). P values <0.05 were accepted as statistically significant.
Results

We first investigated the combined effects of androgen and IGF-I on regulation of ovarian steroidogenesis using rat primary granulosa cells isolated from immature female rat ovaries. In order to exclude the effect of conversion of testosterone to estradiol [16], we utilized DHT, instead of testosterone, as an androgen for assessment of the appropriate AR action.

As shown in Fig. 1, individual treatment with IGF-I (100 ng/ml) or DHT (100 nM) did not affect basal levels of estradiol (Fig. 1A) and progesterone (Fig. 1B) production by rat granulosa cells for 48-h culture. Treatment with IGF-I (0 to 300 ng/ml) increased FSH (10 ng/ml)-induced estradiol production (Fig. 1A) as well as progesterone production (Fig. 1B) by granulosa cells in a concentration-responsive manner. Treatment with DHT (100 nM) only marginally increased estradiol production in the presence of FSH plus IGF-I (0 to 300 ng/ml) (Fig. 1A). On the other hand, it was of note that DHT (100 nM) treatment significantly enhanced FSH-induced progesterone production in the
presence of IGF-I (0 to 300 ng/ml) (Fig. 1B).

To confirm the effects of androgen and IGF-I on steroidogenesis, we examined the mRNA levels of steroidogenic enzymes including StAR, P450scc, 3βHSD and P450arom by quantitative real-time PCR. We previously reported that treatment with IGF-I enhances FSH-induced expression of StAR, P450scc, 3βHSD and P450arom in rat granulosa cells [17]. In the present study, we focused on the effects of androgen on steroidogenic enzyme expression induced by FSH and IGF-I. As shown in Fig. 2, co-treatment with DHT (100 nM) further enhanced the effects of IGF-I (100 ng/ml) on expression of StAR, P450scc and 3βHSD mRNAs induced by FSH (10 ng/ml) in rat granulosa cells for 48 h (Fig. 2A). On the other hand, in accordance with the results for estradiol production (Fig. 1A), the mRNA levels of P450arom were not significantly altered under the condition of the same treatment with DHT and IGF-I (Fig. 2A).

To determine the mechanism by which androgen and IGF-I regulate FSH-induced steroidogenesis by granulosa cells, cAMP synthesis in the conditioned medium of rat granulosa cell culture was examined. FSH (10
ng/ml)-induced cAMP synthesis was not significantly increased by only IGF-I (100 ng/ml) treatment, whereas co-treatment with DHT (100 nM) significantly enhanced the cAMP synthesis induced by FSH and IGF-I by rat granulosa cells for 48-h culture (Fig. 2B), being in accordance with the changes in progesterone production induced by DHT (Fig. 1B). To determine the mutual interaction between the effects of androgen and IGF-I in granulosa cells, the expression levels of IGF-IR and AR were examined by quantitative PCR. As shown in Fig. 2C, the expression level of AR mRNA was upregulated by IGF-I (100 ng/ml) treatment; on the other hand, the expression of IGF-IR was in turn suppressed by DHT (100 nM) treatment for 48-h culture in rat granulosa cells.

We next examined the interaction of androgen, IGF-I and BMP-receptor signaling in rat granulosa cells. As shown in Fig. 3A, stimulation with BMP-6 (100 ng/ml) for 1 h readily induced Smad1/5/8 phosphorylation, which was significantly suppressed by IGF-I (100 ng/ml), DHT (100 nM) or their combined treatment. To clarify the changes in BMP-receptor signal transduction caused by IGF-I and DHT, we also assessed mRNA level of the
BMP target gene Id-1. As shown in Fig. 3B, IGF-I (100 ng/ml) and DHT (100 nM) had no effect on the basal Id-1 mRNA level; however, the Id-1 induction caused by BMP-6 (100 ng/ml) was clearly suppressed by treatment with IGF-I, DHT or their combination for 24-h culture of rat granulosa cells.

To determine the mechanism by which androgen suppresses BMP-Smad signaling in granulosa cells, we further evaluated the changes in BMP-receptor expression caused by androgen and IGF-I treatment. As shown in Fig. 3C, the expression levels of type-I (ALK-2 and ALK-6) and type-II (ActRII) receptors for BMP-6 were reduced by DHT (100 nM) treatment for 48-h culture, in which ALK-6 and ActRII were also decreased by IGF-I (100 ng/ml) treatment. The expression level of another type-II receptor, BMPRII, was not significantly changed by DHT treatment, although the effect was different from that induced by IGF-I. We also assessed changes in the expression of inhibitory Smads including Smad6 and Smad7. As shown in Fig. 3C, the expression levels of Smad6 and Smad7 mRNA were significantly increased by IGF-I (100 ng/ml) and DHT (100 nM), respectively, in rat granulosa cells for 48 h.
Discussion

In the present study, we hypothesized that a high androgenic environment and increased IGF-I activity are mutually involved in the dysregulation of steroidogenesis in PCOS, leading to ovulation disorders. By using rat primary granulosa cell culture, it was revealed that the combined effect of androgen and IGF-I promoted FSH-induced progesterone production, compared with estradiol production, by suppressing endogenous BMP signaling (Fig. 4).

The ovarian IGF-I system plays key roles in normal folliculogenesis and also in the degenerative process of follicular atresia [18, 19], in which IGF-I is involved in the enhancement of FSH sensitivity by upregulating FSH receptor (FSHR) expression on granulosa cells. The significance of IGF-I activity in the development of PCOS pathology and enhanced IGF-IR expression during early preantral development has been reported [2]. On the other hand, roles of androgen and its receptor AR in the pathophysiology of PCOS have also been recognized [20]. AR is expressed in oocytes, granulosa cells and theca cells of
preantral follicles in the rat ovary, in which the expression pattern of AR is different depending on the development stage of follicles [20]. In the present study, it was found that IGF-I treatment upregulated the expression of AR mRNA, while androgen treatment in turn suppressed the expression of IGF-IR mRNA in rat granulosa cells. An androgen excess is clinically related to insulin resistance and/or metabolic syndrome in women [21]. In rodents, long-term treatment with DHT has been demonstrated to cause various reproductive and metabolic features of PCOS. For instance, DHT-treated rodents exhibited reduced ovulation with polycystic changes of the ovaries encompassing atretic follicles, thickened theca and thinned granulosa cells [22-24], suggesting a direct effect of AR actions on the development of reproductive and metabolic features of PCOS but with species-dependent differences.

Relationships between androgen and ovarian growth factors have been reported for IGFs and transforming growth factor (TGF) \( \beta \) superfamily members. In addition to the synergistic effects of androgen and FSH, androgen enhances the proliferation of granulosa cells induced by IGF-I alone or GDF-9 in the
presence of IGF-I [25, 26]. Direct AR effects also enhance the differentiation of rat granulosa cells, with testosterone acting via the AR to increase the expression of P450arom and P450scc [27]. The expression levels of factors for the oocyte–granulosa cell regulatory loop, such as Kit ligand, BMP-15 and GDF-9, are reduced in AR-deficient mouse ovaries at the preovulatory stage [28]. Pathophysiological involvement of BMP system molecules in PCOS has also been reported [9, 29, 30]. Of interest, female GDF-9-knockout mice showed PCO-like morphological features of the ovaries containing ovarian follicular cysts lined by several layers of flattened granulosa cells [31]. Examination of ovarian tissues derived from PCOS patients clarified that GDF-9 expression was significantly delayed and weakened during the differentiation phase [9]. Therefore, it is presumed that ovarian growth factors such as GDFs and BMPs are directly linked to the functional and morphological changes shown in PCOS.

We previously reported that the ovarian growth hormone (GH)/IGF-I system acts to modulate steroidogenesis in rat granulosa cells [17]. IGF-I impaired BMP-Smad1/5/8 signaling via downregulation of the expression of
BMP receptors [17], while BMPs also counteracted GH receptor, IGF-I and IGF-IR expression in rat granulosa cells. The mutual interaction between GH/IGF-I and BMP activities may be critical for the regulation of follicular steroidogenesis. However, the impact of androgen, in relation to IGF-I activity, on ovarian steroidogenesis and its mechanism remain uncertain. In the present study, we further demonstrated that androgen and IGF-I interaction reinforced progesterone production induced by FSH in rat granulosa cells. In addition, IGF-I enhanced the expression of AR, while androgen suppressed the expression of IGF-IR, suggesting the presence of a negative feedback loop within rat granulosa cells.

Clinical investigations have shown that the expression of BMP-6 mRNA was significantly increased in human granulosa cells isolated from PCOS patients in comparison with that in granulosa cells from control patients who underwent in vitro fertilization [10, 11]. Since BMP-6 expression is abundant in granulosa cells of healthy growing follicles but not in atretic follicles in the human ovary [32], the overexpression of BMP-6 in granulosa cells may indicate the
existence of growth-disturbed follicles in PCOS ovaries. Alternatively, the upregulation of BMP-6 in granulosa cells isolated from PCOS patients may reflect the existence of a feedback mechanism caused by suppression of BMP-Smad signaling under the influence of excess androgen and IGF-I.

Collectively, the results indicate that androgen enhances IGF-I-induced progesterone production by counteracting endogenous BMP-6 actions in granulosa cells (Fig. 4), which might be functionally linked to the altered steroidogenic property shown in the PCOS ovary. In this regard, we earlier reported the activity of melatonin, which has been shown to be effective for the infertility of PCOS [33], on ovarian steroidogenesis [34]. In that study, it was found that melatonin plays an antagonistic role in BMP-6 actions in rat granulosa cells. Since BMP-6 has the property of a luteinization inhibitor in growing follicles, the results indicated that melatonin maintains progesterone synthesis and luteinization by inhibiting BMP-6 activity in rat granulosa cells. Such inhibitory effects of melatonin or androgen on BMP-6 activity could be effective for compensating the impaired progesterone production and the arrest of
follicular development observed in PCOS cases. Based on the present findings, it is suggested that balanced intensities between androgen/IGF-I and the BMP system are physiologically critical for fine-tuning ovarian steroidogenesis in growing follicles (Fig. 4).

Fig. 4. Possible mechanism by which androgen and IGF-I regulate ovarian steroidogenesis in rat granulosa cells. DHT promotes FSH-induced progesterone production in the presence of IGF-I action by inhibiting the BMP system in cooperation with each other. IGF-I and DHT suppress Smad1/5/8
signaling by downregulating ALK-2, -6 and ActRII, and upregulating Smad6/7. IGF-I upregulates AR expression, while DHT downregulates IGF-I receptor expression. The combined effects of androgen and IGF-I counteract endogenous BMP-6 activity in rat granulosa cells.
